**Abstract:** Because underwater sensor networks (USNs) have limited energy resources due to environmental constraints, it is essential to improve energy utilization. For this purpose, an autonomous underwater vehicle (AUV) with greater onboard computation power is utilized to process measurement data, and the mobility of the AUV is leveraged to optimize the USN topology, enhancing tracking accuracy. First, to address the transmission delay of underwater acoustic signals, a centralized extended Kalman filter incorporating a time delay estimation (TD-CEKF) algorithm is proposed. Next, the mathematical relationship between AUV position and USN topology is established, based upon which the optimization target is constructed. Subsequently, the penalty function is introduced to remove the constraints from the objective function, and the optimal AUV position is searched using the gradient descent method to optimize the USN topology. The simulation results demonstrate that the proposed algorithm can effectively overcome the influence of transmission delay on tracking and achieve improved tracking performance.

## 1 Introduction

With the increasing emphasis on marine resources and security, the Internet of Underwater Things (IoUT) has gradually started to take shape (Jahanbakht et al., 2021). As an early practical form of IoUT, USNs have been widely used in underwater resource exploration, marine environmental monitoring, and marine military applications (Alostad, 2020; Mohsan et al., 2022). Among them, target tracking technology based on USNs has become a

research hotspot due to its stealth, low cost, and flexibility, and it has been applied in scenarios such as diver navigation, underwater search and rescue, and hostile target monitoring (Tang et al., 2024). Target tracking technology based on USNs faces two main challenges—the complex underwater acoustic environment, characterized by narrow bandwidth and significant transmission delays, which makes tracking difficult, and energy constraints on USN nodes, which cannot have their batteries replaced, resulting in a limited lifetime. The problem of limited bandwidth resources in underwater acoustic channel communication can be addressed by improving the communication bandwidth utilization rate. Zhang S et al. quantized the sensor communication data to reduce the communication bandwidth occupation and improved the quantization error by selecting the quantization bounds (Zhang et al., 2017). Luo J et al. further improved the underwater target tracking per-

formance by selecting different quantization bits for different sensor nodes (Luo et al., 2019). Zhang Q et al. derived the Cramer–Rao lower bound under quantized measurements and used it as an optimization objective to select the best fusion node to improve the tracking performance (Zhang et al., 2014). To address the issue of transmission delays in underwater acoustic signals, Su J et al. considered the impact of transmission delay of ranging echoes and proposed an unscented Kalman filter (UKF) fusion method based on delay estimation (Su et al., 2020). On this basis, Zhang Z et al. further improved the calculation of transmission delay and proposed an improved asynchronous fusion method for particle filter (Zhang et al., 2023).

There has been much research targeting improvements in the energy utilization of USNs. Li Y et al. used the topological structure and energy consumption of nodes as indicators to select neighboring nodes for participation in tracking, thereby reducing energy consumption while meeting tracking accuracy requirements (Li et al., 2024). Zhang D et al. studied the relationship between node transmission energy consumption and the Fisher information matrix (FIM), upon the basis of which the energy of sensor nodes in a period of time is reasonably allocated (Zhang et al., 2018). Tian S et al. considered the errors caused by the positional uncertainty of USNs. Using the FIM, mutual information, and the number of nodes as objectives, they employed the Non-dominated Sorting Genetic Algorithm II (NSGA-II) and the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) to select specific nodes for participation in the tracking process, thereby reducing the energy consumption of the sensor network (Tian and Zhang, 2022). Zheng L et al. proposed a reinforcement learning sensor node selection scheme to achieve a balance between tracking accuracy and energy consumption through a trained D3QN network (Zheng et al., 2023). Zhang D et al. fully mined the information of measured values, calculated the mutual information of sensor nodes, and proposed a data fusion method based on mutual information weighting (Zhang D et al., 2018).

Most of the above studies focus on traditional fixed USNs, where the nodes are immobile, and the coverage area and battery capacity are limited. However, AUVs have seen relatively mature appli-

cations in scientific research, civilian use, and military fields (Zhang et al., 2022; Wang et al., 2024; Xu and Guo, 2022; Xu et al., 2022). Compared to fixed USN nodes, AUVs have the capability of free movement and possess stronger computing power. More importantly, AUVs can surface for recovery and recharge after completing their tasks. Therefore, by introducing AUVs into the tracking process, USN nodes' energy consumption can be reduced, and the tracking performance can be improved. At present, the research on AUV underwater target tracking applications is basically centered around single AUV or multi-AUV collaboration (Chen et al., 2022a; 2022b), and there is little research on the joint tracking by AUV and USN nodes (Song et al., 2022). Although Tian S et al. used AUV's mobility and computing power to act as a fusion center in the proposed tracking method, their research did not take into account the influence of the AUV's own position change on the USN topology (Tian and Zhang, 2021).

Although the aforementioned literature on delay estimation fusion has effectively improved underwater target tracking through particle simulation of acoustic transmission delays, tracking methods based on particle Monte Carlo simulation and unscented transformation require extensive computation. This places high demands on the computational capabilities of USNs, making it difficult to meet the requirements of practical engineering applications. The aforementioned research on improving the energy efficiency of USNs has greatly enhanced energy utilization during target tracking. However, these studies primarily focus on traditional fixed USNs, with relatively few, less in-depth investigations into the collaboration between AUVs and USNs. Motivated by this, a target tracking method involving the collaboration between AUVs and USNs is proposed in this paper. On the basis of using an AUV's computing power to make it a fusion center, the AUV is used as a tracking node to reduce the number of USN nodes participating in tracking and improve the lifetime of USNs. Then, the mobility of the AUV is used to form a better topology with the USN nodes involved in tracking to improve the tracking performance.

The main contributions of this paper are as follows:

- 1) A TD-CEKF fusion method for cooperative tracking by AUV and USN nodes is proposed. This

method not only considers the influence of underwater acoustic signal transmission delay but also avoids the simulation of a large number of particles.

2) The mathematical relationship between AUV position coordinates and FIM is derived, and the optimization problem is constructed based on this.

3) An AUV position search algorithm based on gradient descent method is proposed. First, the problem is unconstrained by applying a penalty function, and then the AUV position with the best topology is searched using gradient descent.

The rest of this paper is organized as follows. Section 2 introduces the system model and presents the process of TD-CEKF. In Section 3, the mathematical relationship between the AUV position change and FIM is constructed, and the optimization problem is established. Section 4 proposes an AUV position search algorithm based on the Lagrange multiplier method and the gradient descent method. Section 5 conducts simulation experiments and results analysis on the proposed algorithm. Section 6 summarizes the main work of this paper.

## 2 System model

In this section, the motion model of the target and the measurement model of the sensors are established, and the underwater acoustic signal transmission model and the TD-CEKF are introduced.

### 2.1 USN and underwater target motion model

In this paper, it is assumed that all sensor clocks and measurement times are synchronized and that the measurement information includes timestamps. The target moves in the underwater three-dimensional space, and the state  $\mathbf{X}_k$  of the target at time  $k$  is

$$\mathbf{X}_k = [x_k, v_{x,k}, y_k, v_{y,k}, z_k, v_{z,k}]^T, \quad (1)$$

where  $(x_k, y_k, z_k)$  is the three-dimensional coordinates of the target at time  $k$  and  $(v_{x,k}, v_{y,k}, v_{z,k})$  is the velocity vector of the target.

The motion equation of the target at time  $k$  can be expressed as

$$\mathbf{X}_{k+1} = \mathbf{F}_k \mathbf{X}_k + \mathbf{G}_k \mathbf{w}_k, \quad (2)$$

where  $\mathbf{F}_k$  is the state transition matrix of the target's motion. In USN target tracking, common motion

models include Constant Velocity (CV) and Constant Turn (CT).  $\mathbf{G}_k$  represents the process noise matrix and  $\mathbf{w}_k$  is the zero mean Gaussian white noise. The sampling interval is  $T$ , and the state transition matrix  $\mathbf{F}_k$  of the two motions can be expressed as

$$\mathbf{F}_k^{CV} = \begin{bmatrix} 1 & T & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & T & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & T \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (3)$$

and

$$\mathbf{F}_k^{CT} = \begin{bmatrix} 1 & \sin(\omega T)/\omega & 0 & -[1-\cos(\omega T)]/\omega & 0 & 0 \\ 0 & \cos(\omega T) & 0 & -\sin(\omega T) & 0 & 0 \\ 0 & [1-\cos(\omega T)]/\omega & 1 & \sin(\omega T)/\omega & 0 & 0 \\ 0 & \sin(\omega T) & 0 & \cos(\omega T) & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & T \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}. \quad (4)$$

The process noise matrix  $\mathbf{G}_k$  is

$$\mathbf{G}_k = \begin{bmatrix} T^3/3 & T^2/2 & 0 & 0 & 0 & 0 \\ T^2/2 & T & 0 & 0 & 0 & 0 \\ 0 & 0 & T^3/3 & T^2/2 & 0 & 0 \\ 0 & 0 & T^2/2 & T & 0 & 0 \\ 0 & 0 & 0 & 0 & T^3/3 & T^2/2 \\ 0 & 0 & 0 & 0 & T^2/2 & T \end{bmatrix}. \quad (5)$$

The distance measurement received by the USN node  $i$  or AUV at time  $k$  can be expressed as

$$Z_k^i = h(\mathbf{X}_k) + \mathbf{v}_k = \sqrt{(x_k - x^i)^2 + (y_k - y^i)^2 + (z_k - z^i)^2} + \mathbf{v}_k, \quad (6)$$

where  $(x^i, y^i, z^i)$  is the position coordinate of sensor node  $i$ , and  $\mathbf{v}_k$  is the zero mean Gaussian noise with variance  $R$ .

### 2.2 TD-CEKF

The target tracking algorithms based on USNs can be divided into two types—centralized and distributed (Tang et al., 2024). With the inclusion of AUVs as nodes and fusion centers, their computing power is much higher than that of ordinary USN nodes, and AUVs can surface to replenish power after completing their tasks. Therefore, the centralized fusion method is more suitable for the scenario of joint tracking with AUVs and USNs.

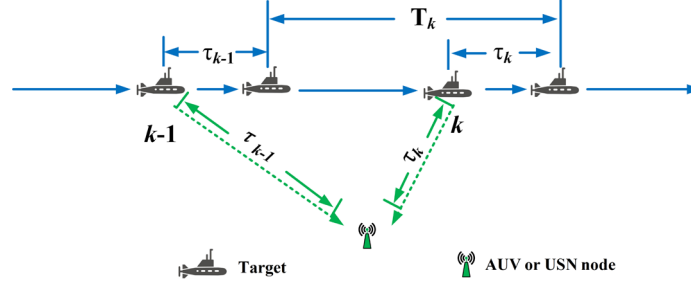

Fig. 1 Schematic diagram of measurement delay

As shown in Fig. 1, the dashed arrows represent measurement information, while the solid arrows indicate the motion of the target. When the sensor receives the measurement of the target at time  $k-1$ , the target has already moved for  $\tau$  seconds. In other words, the measurement information received by the sensor corresponds to the target from  $\tau$  seconds ago. This can lead to a discrepancy between the true position of the target and the measured position. This discrepancy is related to the transmission delay. The transmission delay is

$$\tau_i(\theta_i, \theta_r) = -\frac{1}{\bar{a}} \left( \ln \frac{1 + \sin \theta_r}{\cos \theta_r} - \ln \frac{1 + \sin \theta_i}{\cos \theta_i} \right), \quad (7)$$

where  $\theta_i$  and  $\theta_r$  represent the angle between the acoustic pulse and the horizontal plane at the node  $i$  and the target, respectively, and  $\bar{a}$  is the update coefficient (Zhao et al., 2021).

After obtaining the transmission delay, the predicted state is corrected to:

$$\hat{X}_{k+1|k} = F\hat{X}_k - A_k, \quad (8)$$

where  $A_k$  is the delay correction vector, specifically:

$$A_k = [\tau_k v_{x,k}, 0, \tau_k v_{y,k}, 0, \tau_k v_{z,k}, 0]^T. \quad (9)$$

Thus, the corrected measurement residual is

$$Z_{k+1}^r = Z_{k+1} - h(F\hat{X}_{k+1|k} - A_k). \quad (10)$$

The Jacobian matrix is

$$H_{k+1} = \frac{\partial h(A\hat{X}_{k+1|k} - A_k)}{\partial \hat{X}_{k+1|k}} = \begin{bmatrix} \frac{\hat{x}_{k+1} - x^1}{h(\hat{X}_{k+1})} & 0 & \frac{\hat{y}_{k+1} - y^1}{h(\hat{X}_{k+1})} & 0 & \frac{\hat{z}_{k+1} - z^1}{h(\hat{X}_{k+1})} & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \frac{\hat{x}_{k+1} - x^M}{h(\hat{X}_{k+1})} & 0 & \frac{\hat{y}_{k+1} - y^M}{h(\hat{X}_{k+1})} & 0 & \frac{\hat{z}_{k+1} - z^M}{h(\hat{X}_{k+1})} & 0 \end{bmatrix} \quad (11)$$

In summary, the process of the proposed TD-CEKF is shown in Algorithm 1:

---

#### Algorithm 1: Proposed TD-CEKF algorithm

---

1. Get the original measurement information
  2. **for**  $i=1$  to  $M$  **do**
  3. Compute  $\tau_i$  by (7)
  4. **end for**
  5. Correct the state prediction by (9)
  6. Covariance forecasting:  $P_{k+1|k} = F_k P_k F_k^T + G_k w_k$
  7. Calculate the Jacobian matrix using (11)
  8. State update:  $\hat{X}_{k+1} = \hat{X}_{k+1|k} + K_{k+1} Z_{k+1}^r$
  9. Covariance update:  $P_{k+1} = P_{k+1|k} + K_{k+1} H_{k+1} P_{k+1|k}$

### 3 Problem construction

In this section, the mathematical relationship between the AUV's position and the FIM is derived, and the AUV position optimization problem is established using the AUV's movement range as a constraint.

#### 3.1 Relationship between AUV position and FIM

According to Bayesian estimation theory, the mean square error of target state estimation cannot be lower than the Cramér–Rao lower bound (Yuan et al., 2024; Teimouri and Hoseini, 2024).

$$E \left\{ \left[ \hat{X}_k - X_k \right] \left[ \hat{X}_k - X_k \right]^T \right\} \geq J_k^{-1}(X_k), \quad (12)$$

where  $J_k^{-1}(X_k)$  is the FIM and  $\hat{X}_k$  is the estimated state of the target. The FIM of the target at time  $k$  is expressed as

$$J_k(X_k) = -E_{p(Z_k, X_k | Z_{1:k-1})} \left[ \nabla_{X_k}^{X_k} \ln p(Z_k, X_k | Z_{1:k-1}) \right], \quad (13)$$

where  $\nabla_{\eta}^k = \nabla_{\eta} \nabla_{\eta}^T$  denotes the second-order partial derivative operator.  $p(Z_k, X_k | Z_{1:k-1})$  is the joint probability density of the measurement, which can be decomposed into (Luo and Han, 2019).

$$p(\mathbf{Z}_k, \mathbf{X}_k | \mathbf{Z}_{1:k-1}) = p(\mathbf{Z}_k | \mathbf{X}_k) p(\mathbf{X}_k | \mathbf{Z}_{1:k-1}). \quad (14)$$

Therefore,  $\mathbf{J}_k(\mathbf{X}_k)$  can be decomposed into

$$\mathbf{J}_k(\mathbf{X}_k) = \mathbf{J}_k^p(\mathbf{X}_k) + \mathbf{J}_k^s(\mathbf{X}_k), \quad (15)$$

where  $\mathbf{J}_k^p(\mathbf{X}_k)$  is related to prior information and  $\mathbf{J}_k^s(\mathbf{X}_k)$  is related to predictive data. The specific calculation methods are as follows (Shi et al., 2020):

$$\begin{aligned} \mathbf{J}_k^p(\mathbf{X}_k) &= -E_{p(\mathbf{X}_k | \mathbf{Z}_{1:k-1})} \left[ \nabla_{\mathbf{X}_k}^{X_k} \ln p(\mathbf{X}_k | \mathbf{Z}_{1:k-1}) \right] \\ &\approx \Sigma_{X_k}^{-1} \end{aligned} \quad (16)$$

$$\begin{aligned} \mathbf{J}_k^s(\mathbf{X}_k) &= -E_{p(\mathbf{Z}_k | \mathbf{X}_k)} \left[ \nabla_{\mathbf{X}_k}^{X_k} \ln p(\mathbf{Z}_k | \mathbf{X}_k) \right], \\ &= \mathbf{D}_k^T \Sigma_{Z_k}^{-1} \mathbf{D}_k \end{aligned} \quad (17)$$

where  $\Sigma_{X_k}$  is the error covariance matrix,  $\Sigma_{Z_k}$  is the measurement noise matrix, and  $\mathbf{D}_k = \left[ \nabla_{X_k} h(\mathbf{X}_k) \right]^T$  is the Jacobian matrix. Therefore, the relationship between AUV position  $\mathbf{u} = (x^A, y^A, z^A)$  and FIM is

$$\begin{aligned} \mathbf{J}_k(\mathbf{X}_k, \mathbf{u}) &= \mathbf{J}_k^p(\mathbf{X}_k, \mathbf{u}) + \mathbf{J}_k^s(\mathbf{X}_k, \mathbf{u}) \\ &= \Sigma_{X_k}^{-1} + \mathbf{D}_k^T \Sigma_{Z_k}^{-1} \mathbf{D}_k \\ &= \Sigma_{X_k}^{-1} + \frac{1}{h^2(\mathbf{X}_k^A)R} \begin{bmatrix} A^2 & 0 & AB & 0 & AC & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ BA & 0 & B^2 & 0 & BC & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ CA & 0 & CB & 0 & C^2 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \end{aligned} \quad (18)$$

where  $A = x_k - x^A$ ,  $B = y_k - y^A$ ,  $C = z_k - z^A$ . The state  $\mathbf{X}_k$  of the target is always unknown in the tracking process, so here,  $\mathbf{X}_k$  is replaced by the estimated state  $\hat{\mathbf{X}}_k$ .

### 3.2 AUV position optimization problem construction

According to the mathematical relationship between the AUV's position and the FIM matrix, the change in the AUV's position affects the lower bound of target state estimation. It is assumed that the displacement vector of the AUV in three-dimensional space is  $\Delta \mathbf{u} = (\Delta x^A, \Delta y^A, \Delta z^A)$ ; thus, the FIM at time  $k$  can be expressed as a function of the displacement vector  $\mathbf{J}_k(\mathbf{X}_k, \mathbf{u} + \Delta \mathbf{u})$  and the predicted value  $\mathbf{X}_k$ . For each tracking time step, the predicted value remains unchanged after the data fusion is completed, so the

FIM is only related to the displacement vector. By selecting the AUV displacement vector for the next moment, the FIM can be increased, which is equivalent to reducing the lower bound of the mean square estimation error. Therefore, the objective function of the AUV position optimization problem is constructed as follows:

$$\begin{aligned} &\arg \max_{\Delta \mathbf{u}} \log \det [\mathbf{J}_k(\Delta \mathbf{u})] \\ &s.t. \begin{cases} |\Delta x^A| \leq v_x T \\ |\Delta y^A| \leq v_y T \\ |\Delta z^A| \leq v_z T \end{cases} \end{aligned} \quad (19)$$

where  $v_x$ ,  $v_y$ , and  $v_z$  are the velocity components of AUV in three dimensions, respectively, and  $T$  is the sampling interval. The constraint is the maximum distance the AUV can move within the sampling interval (AUV speed  $v$  multiplied by the sampling interval  $T$ ). For ease of calculation, the AUV's speed is decomposed into three-dimensional components. For FIM, the D-criterion is used in this paper (Moreno-Salinas et al., 2013), and the logarithm of the determinant value of FIM is used to facilitate the solution process later.

## 4 The solution of AUV position

In this section, the Lagrange multiplier method is used to remove the constraints from the objective function, and the optimal position of the AUV is solved by using the gradient descent method.

For the form of (18), it has been proved to be a convex problem (Zhang and Tian, 2023). Due to the relatively simple form of (19) and the high real-time requirements for target tracking, the gradient descent method is employed in this paper, which has a high search efficiency. The problem needs to be unconstrained first. The unconstrained objective function can be constructed using the penalty function method:

$$\begin{aligned} \psi(\Delta \mathbf{u}, \zeta) &= -\log \det [\mathbf{J}_k(\Delta \mathbf{u})] - \zeta [\log(v_x T - \Delta x^A) \\ &\quad + \log(v_x T + \Delta x^A) + \log(v_y T - \Delta y^A) \\ &\quad + \log(v_y T + \Delta y^A) + \log(v_z T - \Delta z^A) \\ &\quad + \log(v_z T + \Delta z^A)] \end{aligned} \quad (20)$$

where  $\zeta$  is the penalty factor. Since the gradient descent method is used, the objective function is nega-

tive in (20), and the maximization problem is transformed into a minimization problem.

According to the properties  $\frac{\partial \log \det(\mathbf{Q})}{\partial q} = \text{tr} \left\{ \mathbf{Q}^{-1} \frac{\partial \mathbf{Q}}{\partial q} \right\}$ , the gradient of  $\psi(\Delta \mathbf{u}, \zeta)$  is

$$\nabla_{\Delta \mathbf{u}} \psi(\Delta \mathbf{u}, \zeta) = [\nabla_{\Delta x} \psi(\Delta x^A, \zeta), \nabla_{\Delta y} \psi(\Delta y^A, \zeta), \nabla_{\Delta z} \psi(\Delta z^A, \zeta)], \quad (21)$$

where  $\nabla_{\Delta x} \psi(\Delta x^A, \zeta)$  is written as Eq. (22) (on the bottom of this page).

Similarly, we can obtain

$$\nabla_{\Delta y} \psi(\Delta y^A, \zeta) = -\text{tr} \left[ \mathbf{J}_k^{-1}(\Delta \mathbf{u}) \frac{\partial \mathbf{J}_k(\Delta \mathbf{u})}{\partial \Delta y^A} \right] - \zeta \left( \frac{1}{v_y T - \Delta y^A} + \frac{1}{v_y T + \Delta y^A} \right) \quad (22)$$

$$\nabla_{\Delta z} \psi(\Delta z^A, \zeta) = -\text{tr} \left[ \mathbf{J}_k^{-1}(\Delta \mathbf{u}) \frac{\partial \mathbf{J}_k(\Delta \mathbf{u})}{\partial \Delta z^A} \right] - \zeta \left( \frac{1}{v_z T - \Delta z^A} + \frac{1}{v_z T + \Delta z^A} \right). \quad (23)$$

After obtaining the gradient vector, the gradient descent method can be used to search. The overall search process is shown in Algorithm 2.

$H(\mathbf{u})$  represents the augmented part of the objective function. Combined with the above, the overall flow chart is shown in Fig. 2. The USN nodes and AUV first receive the measurement echo, and then each USN node transmits the measurement value to the AUV. The measurement data have a flag bit so that the AUV can distinguish the source of the meas-

determine the AUV's new position coordinates and initiate movement. This process is repeated at each subsequent time step until the tracking task is completed. After each movement, the AUV checks if it has sufficient energy to complete the next tracking operation. If not, it will return to the surface for recharging. After this, the USN nodes will continue to carry out the tracking task.

---

#### Algorithm 2: AUV position search algorithm

---

Select the initial value, set  $\zeta > 0$ ,  $\eta > 1$ ,  $k = 1$ ,  $L = 0$ ,  $0 \leq \varepsilon_1 \leq 1$ ,  $0 \leq \varepsilon_2 \leq 1$ ,  $\vartheta \in (0, 1)$ .

Step1: Calculate gradient  $g_L = -\nabla_{\Delta \mathbf{u}} \psi(\Delta \mathbf{u}, \zeta)$ .

Step2: If  $|g_L| \leq \varepsilon_1$ , then  $\Delta \mathbf{u}_k^* = \Delta \mathbf{u}_L$ , go to Step6.

Step3: Use the linear backtracking method to determine the step length  $\alpha_L$ .

Step4: Let  $\Delta \mathbf{u}_L = \Delta \mathbf{u}_L + \alpha_L g_L$ .

Step5: Let  $L = L + 1$ , go to Step1.

Step6: If  $\zeta H(\mathbf{u}) \leq \varepsilon_2$ , then output  $\Delta \mathbf{u}^* = \Delta \mathbf{u}_k$ , otherwise go to Step7.

Step7: Let  $\sigma_{k+1} = \eta \sigma_k$ .

Step8: Let  $k = k + 1$ , go to Step1.

---

## 5 Simulation and analysis

In this section, simulation experiments are conducted to validate the effectiveness of the proposed algorithm. The parameters are set as follows: the monitoring duration is 50 time steps, the sampling interval  $T$  is 1s, the observation noise  $R$  is 5, and the

$$\begin{aligned} \nabla_{\Delta x} \psi(\Delta x^A, \zeta) &= -\text{tr} \left[ \mathbf{J}_k^{-1}(\Delta \mathbf{u}) \frac{\partial \mathbf{J}_k(\Delta \mathbf{u})}{\partial \Delta x^A} \right] - \zeta \left( \frac{1}{v_x T - \Delta x^A} + \frac{1}{v_x T + \Delta x^A} \right) \\ &= -\text{tr} \left\{ \mathbf{J}_k^{-1}(\Delta \mathbf{u}) \left[ \mathbf{J}_k^U \frac{2(x_k - \Delta x^A)}{R h^3(\mathbf{X}_k^A)} + \frac{1}{R h^2(\mathbf{X}_k^A)} \begin{bmatrix} -2(x_k - \Delta x^A) & 0 & -(y_k - \Delta y^A) & 0 & -(z_k - \Delta z^A) & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ -(y_k - \Delta y^A) & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ -(z_k - \Delta z^A) & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \right] \right\} \quad (24) \end{aligned}$$

urement value. Upon acquiring the measurement data, the AUV executes Algorithm 1 to obtain the target's predicted state, followed by executing Algorithm 2 to

process noise variance coefficient  $q^2 = 10^{-2}$ . The target motion follows a CT model with a turn rate  $\omega$  of 0.15rad/s, and the underwater acoustic signal propa-

gation speed is 1473m/s. The initial state of the target is  $X_1 = [150, 5, 100, 5, 32, 5]^T$ , the initial estimated state is  $\hat{X}_1 = [151, 5, 98, 5, 32, 5]^T$ , and the update coefficient  $\bar{a} = 0.017$ . In the first part of the simulation, four underwater sensor nodes are set. Their coordinates are (40, 10, 10), (70, 80, 80), (65, 70, 40), and (60, 90, 20).

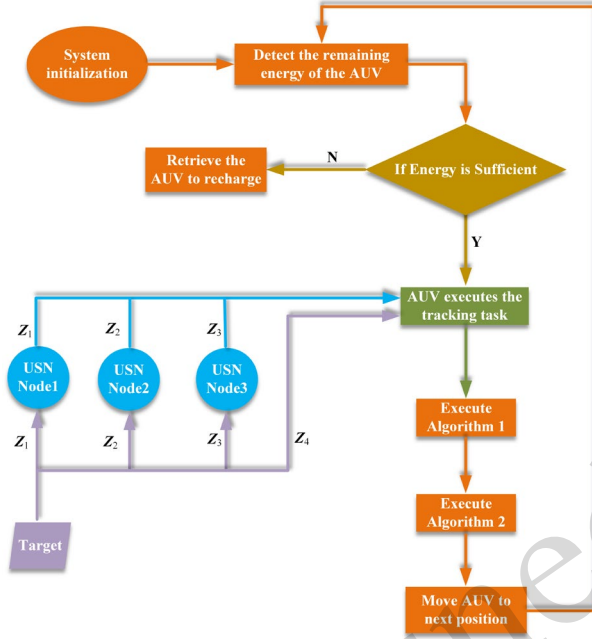

Fig. 2. Flow chart of proposed joint tracking

The setting parameters of the tracking scenarios are summarized in Table 1. In this paper, the root mean square error (RMSE) of the target state estimation is used as an accuracy measure of state estimation. At time  $k$ , the RMSE of the estimation  $\hat{X}_k$  of the target state  $X_k$  is

$$RMSE_k = \sqrt{\frac{\sum_{i=1}^{MC} \|X_k - \hat{X}_k\|^2}{MC}}, \quad (25)$$

where  $MC$  is the number of Monte Carlo experiments. To avoid contingency, all simulation experiments in this paper were conducted 200 times.

The first simulation involves the TD-CEFK algorithm proposed in Section 2. The comparison algorithms are the time offset estimation unscented Kalman filter fusion (TO-UKF) (Su et al., 2020) and the improved time delay estimation particle filter (PA-PF) algorithms (Zhang et al., 2023). The two particle filter algorithms use a sequential importance

resampling (SIR) particle filter; to fully verify the effectiveness of the algorithm, the number of particles is set to 1000. Fig. 3 shows the comparison of the estimated path of each algorithm for target tracking. Compared with the estimated paths of TO-UKF and PA-PF, the estimated path obtained by this algorithm is closer to the true path of target motion.

Table 1 Parameters used for the simulation

Parameter	Value
Sampling interval, $T$	1s
Tracking duration	50s
Covariance of measurement noise, $R$	5
Intensity of process noise, $q^2$	$10^{-2}$
Turning speed, $\omega$	0.15rad/s
Underwater acoustic signal propagation speed, $c$	1473m/s
Update coefficient, $\bar{a}$	0.0017
Monitored field	200m×100m×600m
Initial position of the target	(150, 100, 32)
AUV navigation speed, $v$	5m/T
Number of USN nodes	4

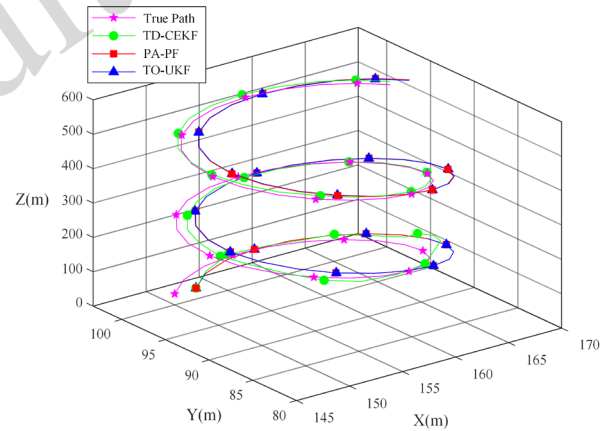

Fig. 3. Underwater tracking scene

Fig. 4(a) and Fig. 4(b) are the transmission delay  $\tau$  at different target speeds and the target position deviation caused by  $\tau$  at different target speeds. The velocity vectors are  $[1, 1, 1]^T$ ,  $[2, 2, 2]^T$  and  $[3, 3, 3]^T$ . In Fig. 4(a), the larger the target's velocity vector, the greater the transmission delay  $\tau$  becomes. From (7), it can be concluded that the  $\tau$  is related to the angle between the acoustic pulse and the horizontal plane at the node and the target. The greater the velocity of the target, the greater the horizontal angle of the ranging acoustic pulse of node 1 at the target, so the greater

the  $\tau$ . Over time, although  $\tau$  moves up and down, the overall trend is increasing. This is because the turning rate of the target under CT motion is relatively large, and the radius is only 10m, which is far less than the range of the target rising. In general, the target is constantly away from node 1. Therefore, the  $\tau$  of the acoustic pulse echo is increasing. In addition, it is found that when the sensor is about 250 m away from the target, the combined speed of the velocity components in each dimension is 40m/s, and the  $\tau$  is about 0.2s, which is far less than the sampling period, and the speed of the underwater target is generally not more than 40 knots (20.57m/s). When the speed of the target becomes faster, the  $\tau$  is constantly increasing, resulting in an increase in the RMSE of the position deviation in Fig. 4(b). It should be noted that the trend of  $\tau$  in Fig. 4(a) is inconsistent with the RMSE of position deviation in Fig. 4(b). This is because Fig. 4(a) shows only the time delay change of USN node 1, while Fig. 4(b) is the position deviation calculated by the time delay of all USN nodes.

Fig. 5 compares the RMSE of each time delay estimation fusion algorithm. The velocity vector of the target in Fig. 5(a) is  $[5, 5, 5]^T$ . It can be seen that the tracking accuracy of the PA-PF algorithm is better than that of the TO-UKF algorithm and the TD-CEKF

algorithm is stabilized, the proposed TD-CEKF algorithm in this paper shows its advantages. From the 20th time step onward, the RMSE of TD-CEKF is lower than that of the other two algorithms, and it remains stable between 1.2 m and 1.5 m. The RMSE of the TO-UKF algorithm in this scenario is lower than that of the PA-PF algorithm. This is because the Unscented Kalman Filter is less prone to particle degeneracy issues, making it more accurate in the particle approximation of transmission delay. The TD-CEKF algorithm has more advantages in time delay estimation by integrating global information.

The velocity vectors of the target in Fig. 5(a) and Fig. 5(b) are  $[7, 7, 7]^T$  and  $[9, 9, 9]^T$ , respectively. In Fig. 5(a), the proposed TD-CEKF still has a better tracking effect than the other algorithms. The TO-UKF algorithm begins to show advantages in the time delay estimation of unscented particles when the speed is large, and its tracking RMSE is better than the PA-PF algorithm, but there is still a certain gap with the proposed TD-CEKF in this paper. The RMSE gap of each algorithm in Fig. 5(c) is larger than that in Fig. 5(a) and Fig. 5(b), and the proposed TD-CEKF still achieves the best tracking performance. Comparing these three diagrams, the PA-PF algorithm estimates the transmission delay through a large number of

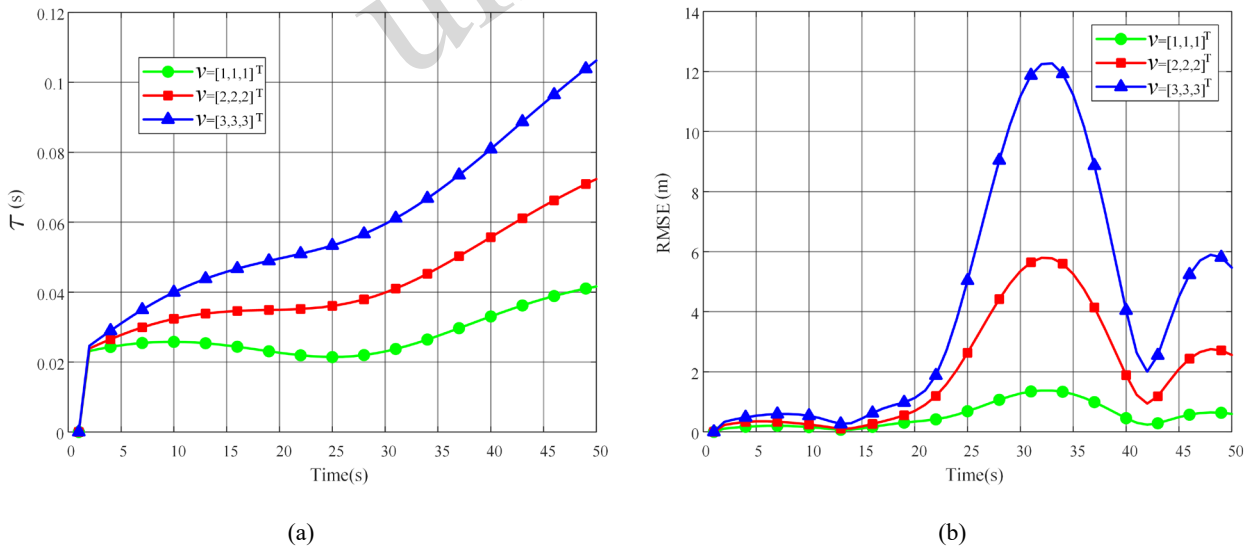

Fig. 4. Comparison of (a) transmission delay and (b) position error at different target speeds

algorithm proposed in this paper at the beginning of the tracking task. However, as the tracking task progresses, the RMSEs of each algorithm begin to rise, and a huge jitter occurs. When the tracking of each

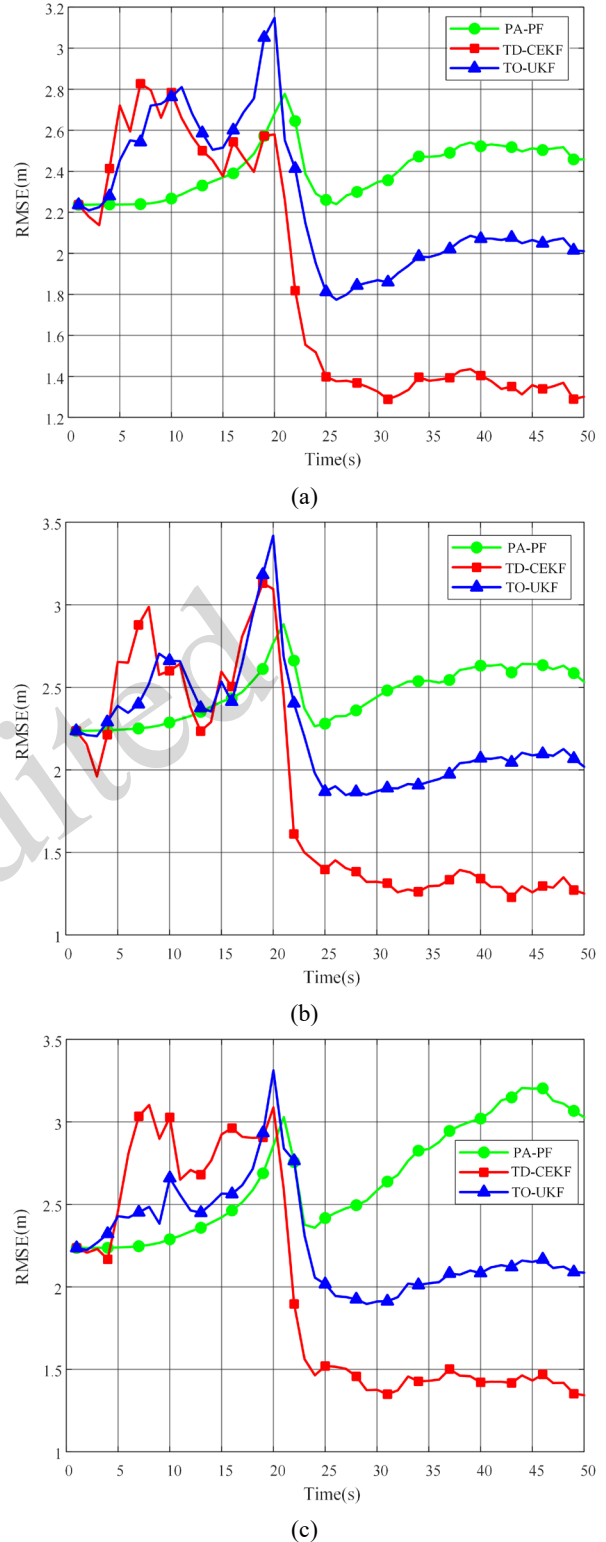

particle approximations, but the particle degradation phenomenon of the particle filter makes the estimation of the delay inaccurate. The TO-UKF algorithm introduces the transmission delay into the sigma par-

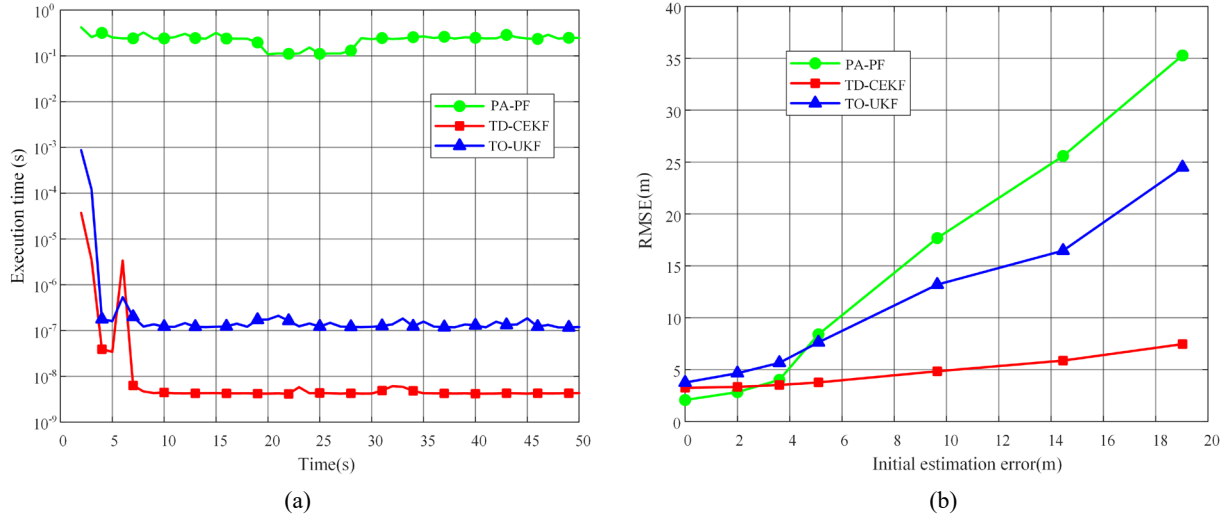

ticle of the unscented transformation, but the unscented transformation has a serious dependence on the accuracy of the initial value estimation, so the performance is not as good as the proposed TD-CEKF when there is an initial error. The proposed TD-CEKF can achieve better tracking results than the estimation algorithm of particle simulation by introducing time delay correction to the centralized Jacobian matrix.

Fig. 6(a) shows the comparison of the execution time of the three time delay fusion algorithms. The operating environment is an Intel(R) Core(TM) i9-13900H CPU running at 2.60GHz. For the convenience of display, Fig. 6(a) shows the results after taking the logarithm of the execution time of each algorithm. It can be seen that neither TD-CEKF nor TO-UKF requires a large number of particles to approximately estimate the delay, so the order of magnitude of the execution time at each time step is much smaller than that of the PA-PF algorithm. It is worth noting that in Fig. 6(a), the order of magnitude of the execution time of the TD-CEKF and TO-UKF algorithms is much smaller than that of the PA-PF algorithm, reaching  $10^{-6}$ s when running on a computer. If running on the CPU of the sensor node, the time consumed will be much higher than  $10^{-6}$ s. In practical engineering applications, the time delay estimation algorithm based on particle filter and unscented transformation has higher requirements on the computing power of the CPU, which makes it difficult to meet engineering application requirements.

Fig. 6(b) shows the average tracking RMSE comparison of each algorithm under different initial estimation errors. The abscissa is a different initial estimation error. It can be seen that the TD-CEKF algorithm is less affected by the initial estimation error, while the TO-UKF and PA-PF algorithms are greatly affected by the initial state. This is because the particle approximation requires high accuracy of the initial estimated state. However, the complex underwater environment determines that the initial estimation error will not be low.

**Fig. 5 RMSE comparison of time delay estimation algorithms under (a)  $v = [5, 5, 5]^T$ ; (b)  $v = [7, 7, 7]^T$ ; and (c)  $v = [9, 9, 9]^T$**

**Fig. 6 Comprehensive comparison of time delay estimation algorithms: (a) Comparison of the execution time; (b) RMSE under different initial estimation errors**

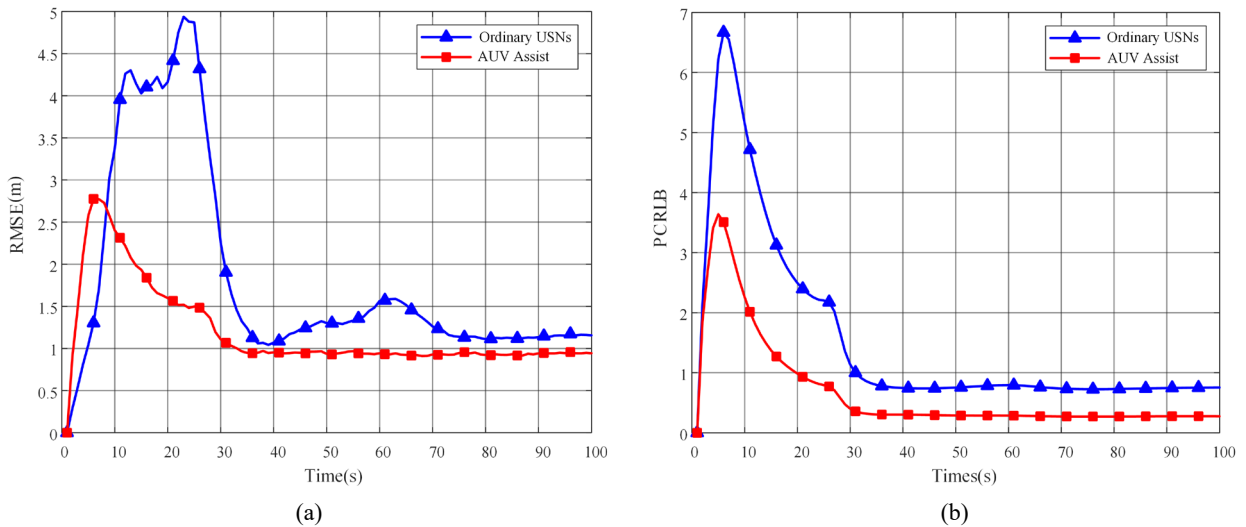

Therefore, by comprehensively comparing the RMSE and execution time of each algorithm, the proposed TD-CEKF is more suitable for application in the field of complex underwater target tracking.

For the AUV position search algorithm proposed in this paper, the simulation is set as follows: the tracking duration is 100 time steps. The target's motion remains as the constant turn (CT) motion shown in Fig. 3, with a turn rate of  $0.15\text{rad/s}$ . This section compares scenarios where four USN nodes participate in tracking. In both algorithms, the positions of the three nodes remain consistent. In order to verify the influence of AUV on the topology, both of them adopt the TD-CEKF algorithm proposed in this paper.

Figs. 7–9 compare the tracking RMSE and pos-

terior Cramér–Rao lower bound (PCRLB) under different process noises. The variance coefficient of process noise in Fig. 7 is  $q^2=10^{-4}$ . It can be seen that, compared with the ordinary USNs, after replacing an ordinary USN node with an AUV, the AUV continuously changes its position according to the proposed algorithm to form a better topology, so the tracking accuracy is significantly higher than that of the ordinary USNs. In addition, the joint tracking by AUV and USN nodes is also more stable in terms of tracking stability. The RMSE gradually stabilizes after the 30<sup>th</sup> time step, while the tracking RMSE of the USN fluctuates greatly due to the fixation of nodes.

Fig. 7(b) more intuitively illustrates the perfor-

**Fig. 7 Comparison of tracking performance before and after optimization ( $q^2=10^{-4}$ ): (a) RMSE; (b) PCRLB**

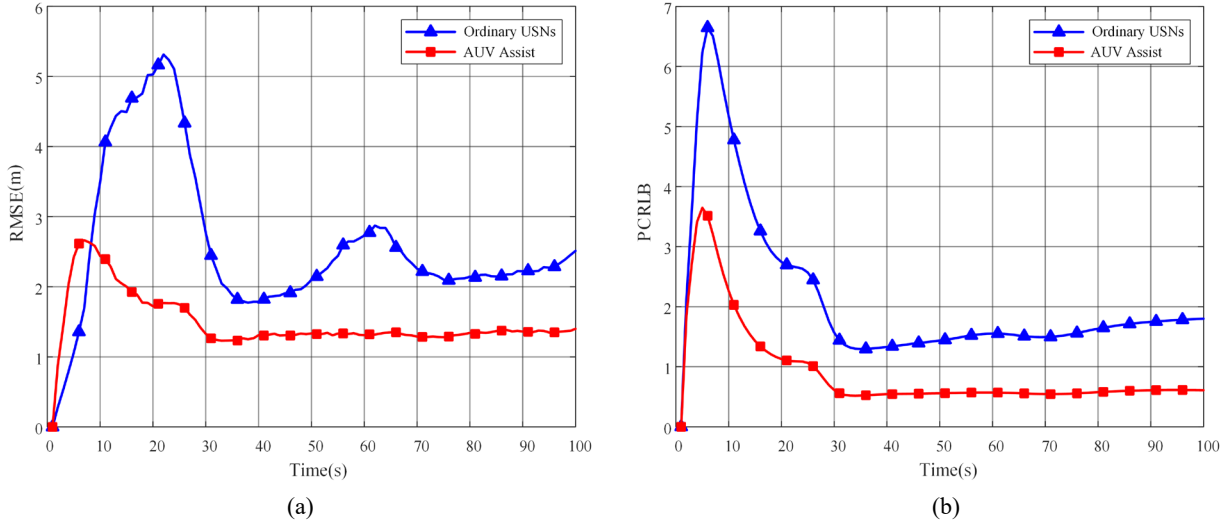

Fig. 8 Comparison of tracking performance before and after optimization ( $q^2=10^{-3}$ ): (a) RMSE; (b) PCRLB

performance of the AUV location search algorithm proposed in this paper. At each time step, the AUV will move to a location with a larger FIM (i.e., a position with smaller PCRLB). Therefore, the PCRLB value after the AUV position moves in Fig. 7(b) is smaller than that of the topology composed of ordinary USN nodes. The process noise variance coefficients in Figs. 8 and 9 are  $q^2=10^{-3}$  and  $q^2=10^{-2}$ , respectively. Through the longitudinal comparison of these three sets of maps, it can be found that with the continuous increase of process noise, both tracking methods are affected to varying degrees, and RMSE and PCRLB increase. However, the tracking based on USN fixed nodes is obviously affected by noise. When the process noise variance coefficient  $q^2=10^{-2}$ , RMSE even

increases from about 1.15 m to about 5 m. The joint tracking method of AUV and USN nodes is less disturbed by noise because the AUV is constantly moving to the larger position of FIM, and the RMSE increases slightly from 0.92 m at  $q^2=10^{-4}$  to about 2 m at  $q^2=10^{-2}$ , which is much smaller than the tracking growth rate based on USN fixed nodes. It can also be seen from the comparison of PCRLB that the proposed joint tracking method in this paper has stronger noise immunity performance. In the actual underwater environment, the noise and reverberation in the underwater acoustic channel are far more serious than those in the land environment. Therefore, the method based on AUV and USN joint tracking is more suitable for underwater target tracking.

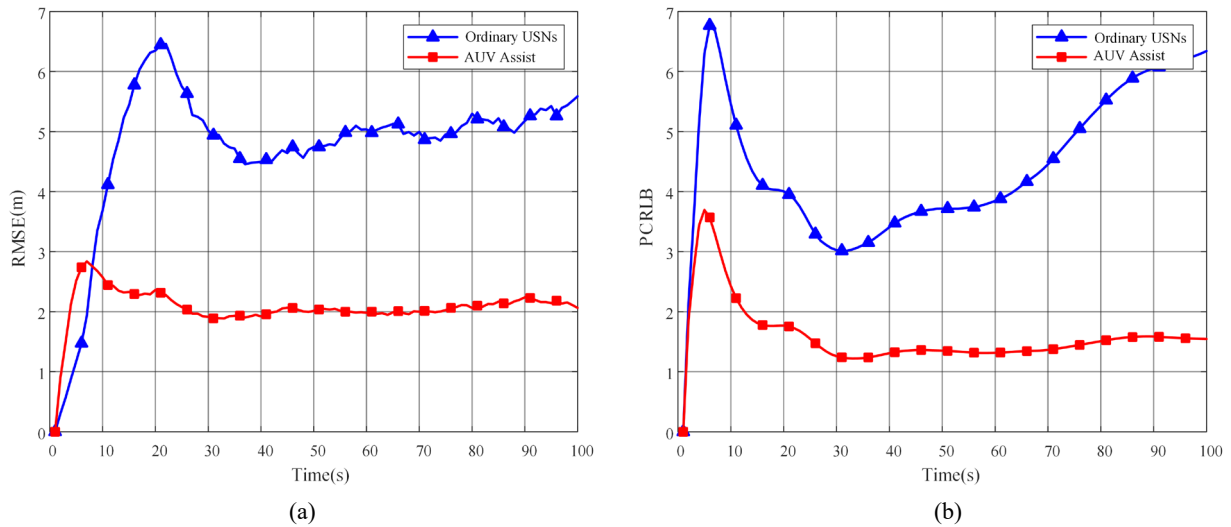

Fig. 9 Comparison of tracking performance before and after optimization ( $q^2=10^{-2}$ ): (a) RMSE; (b) PCRLB

Fig. 10 presents the comparison of execution times between two tracking methods. The tracking based on fixed USN nodes has, on average, a shorter execution time, as it does not require a search algorithm. In contrast, the execution time of the joint tracking algorithm involving AUV and USN is higher due to the need for a gradient descent search for the AUV's position. However, as seen in Fig. 10, the additional time required for searching the AUV's position is relatively small, keeping the execution times of both methods within the same order of magnitude and not significantly different. The proposed AUV and USN joint tracking algorithm is capable of underwater target tracking. Furthermore, since the AUV acts as the fusion center, it reduces the number of sensor nodes involved in tracking and their computational tasks, thereby saving energy and extending the lifespan of the entire sensor network. Unavoidably, the deployment and operation of AUVs also incur costs and energy consumption. However, this is worthwhile compared to the expensive cost and extremely limited, non-recoverable energy resources of USN nodes. In addition, in the joint tracking algorithm proposed in this paper, the AUV's tracking method is based on hydrophone ranging, which is significantly more cost-effective compared to the traditional sonar imaging tracking methods used in AUVs.

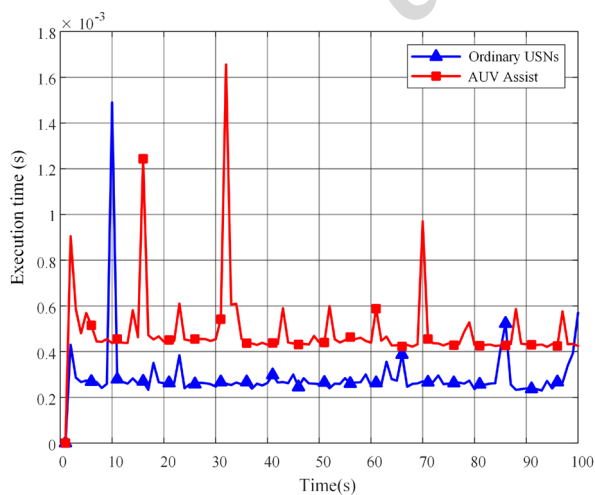

Fig. 10 Comparison of algorithm execution time

## 6 Conclusions

Underwater target tracking using USNs currently faces challenges such as limited energy and underwater acoustic transmission delay. To address these issues, first, the influence of transmission delay on the target tracking is effectively mitigated by the proposed TD-CEKF algorithm. Second, a joint tracking method utilizing both AUV and USN nodes is introduced, which demonstrates better tracking accuracy and noise immunity performance compared to tracking solely using USN nodes. Finally, the simulation results demonstrate that the proposed joint tracking algorithm not only reduces the task load of USN nodes during underwater target tracking but also achieves improved tracking performance. In our future work, we will focus on AUV position optimization with multiple targets and evaluate how asynchronous sensor timing affects tracking.
